THE DESIGN OF A CUSTOM 32-BIT RISC CPU AND PORT TO GCC COMPILER BACKEND

by
DANIELLE MEGAN FISCHER

GRADUATE PAPER

Submitted in partial fulfillment
of the requirements for the degree of
MASTER OF SCIENCE
in Electrical Engineering

Approved by:

Mr. Mark A. Indovina, Senior Lecturer
Graduate Research Advisor, Department of Electrical and Microelectronic Engineering

Dr. Sohail A. Dianat, Professor
Department Head, Department of Electrical and Microelectronic Engineering

DEPARTMENT OF ELECTRICAL AND MICROELECTRONIC ENGINEERING
KATE GLEASON COLLEGE OF ENGINEERING
ROCHESTER INSTITUTE OF TECHNOLOGY
ROCHESTER, NEW YORK
MAY 2020

To everyone who has supported me throughout my college career and will continue to in the future; specifically, my mom, sister, brother, and my closest friends. Thank you to everyone for their love and support during these years.

Abstract

This paper presents the design of a 32-bit RISC processor, which is then mapped to the backend of GCC so basic C code can be compiled successfully to the processor. There are many design decisions that go into the construction of a processor. The instruction set architecture gives away a lot of information regarding the individual instructions that the processor will have, the memory architecture, as well as how I/O peripherals will be handled. Additionally, the hardware implementation of the processor needs to be kept in mind when creating the design. Pipelining can often help with processor speed, while cache implementation can assist in memory speed. After designing the processor, GCC's backend needs to be analyzed to port it to function with the processor's individual opcodes. Once GCC can compile its C code to an assembly language which is able to assemble into machine code that matches up with the opcodes the processor was created for, the machine code can be written into the processor's program memory and executed successfully. This paper also talks about different design decisions that are made during the process of creating a processor, as well as the general makeup of the GCC compilation process.

Declaration

I hereby declare that except where specific reference is made to the work of others, the contents of this paper are original and have not been submitted in whole or in part for consideration for any other degree or qualification in this, or any other University. This paper is the result of my own work and includes nothing which is the outcome of work done in collaboration, except where specifically indicated in the text.

Acknowledgements

I would like to first thank all of my professors at RIT, specifically my EE professors, for supporting me through my college career. First, I'd like to thank Mark Indovina, a mentor and my advisor for this paper, for always having more confidence in me than I did, and for always being ready with a spit of sarcasm. I would also like to thank Dr. Moon for instilling in me my initial interest in digital electronics, Dr. Patru for teaching me everything I know about processor design, Dr. Brown for pushing me to be the best student I can be (and teaching me Circuits 1, a very important fundamental, of course), Dr. Amuso for teaching me that engineering courses can judge you off more than just examinations, and Carlos for making the embedded final humble me and my GPA (and employing me as a TA). I would also like to thank Patti, an amazing BS/MS advisor who always seems to have more on her plate than she can fit, but always finding a way to prioritize the students, and Ken, the EE facilities manager, and my favorite guitar-playing, story-telling guy on floor. Thank you to everyone on the EE floor for an amazing 5 years, I'm so disappointed I didn't get to spend the last few weeks of my senior year with you all.

Of course, I couldn't have done a lot of what I have accomplished without the support of my family. Thank you so much to my mom, for being my best friend and #1 supporter since birth, to my sister, Cassie, for being my other best friend, my #2 supporter since her birth, and for being the coolest sister I've ever had, and to my brother, Billy, for always making me laugh when you call. I love you all so much, and I can't wait to see what your futures bring.

I would also like to thank pretty much everyone that every sat in the TA office for always brightening my day. Special thanks to my main group of EEs, DarDar, DrewBB, Ry Ry, Kev Kev, Andrew, Dania, Dakota, Connor, Dan, Danny, Tommy, John (my mans was always pullin through with the free food), and Adam. Without these guys, my everyday struggle would've been so much less enjoyable.

Last but not least, I would like to thank all my closest friends I've made (or kept) over my years here: Justine, Becca, Dania, Claire, Mandy, Ricky (whom made my college career a much deeper learning experience from having to explain everything to), Ajnur, Alessandro, and Rowan. A special thanks to my boyfriend, Darian, for always making me laugh, even at my lowest and most stressful times, and for being my favorite (and probably only possible) quarantine buddy during coronavirus. I am so fortunate to have such a large support group that makes my acknowledgments section so long. You guys are always there when I need it, and I couldn't be where I am today without you.

Chapter 1

Introduction

The functionality of processors makes them a tool that is used universally. Processors are seen in every piece of technology used on a day-to-day basis. Computers, phones, tablets, robots, cars, anything that “thinks” has a processor at its core, making the most basic of decisions. For every new processor that is designed, there is an assembly language to match. Having a different programming language to learn for every unique processor would be tedious and difficult to manage. Processors would be less ubiquitous. For this reason, it is common for compilers of commonly-used coding languages, like C, C++, Java, etc. to be ported to these processors, so higher level code can be compiled and run on unique processors. This process is explored in this paper. For this project, a 32-bit RISC pipelined processor with cache memory was designed and GCC (GNU C Compiler) was ported to the custom processor to run basic C code.

1.1 Organization

This paper will be organized into 6 chapters. This chapter, Chapter 1, is the introduction. Chapter 2 will talk about the background of processors and compilers, specifically RISC processors

and GNU Compiler Collection. Other processors and compilers will be explored to find their advantages and disadvantages. Next, Chapter 3 will talk about the design of the custom RISC processor used in this project. Chapter 4 will talk about the back end alterations made to GCC, and then Chapter 5 will follow with testing and results of the GCC porting to the custom RISC processor. Finally, Chapter 6 will talk about future work and conclusions of the project.

Chapter 2

Background on Processors and Compilers

This chapter discusses background of processors, specifically RISC and CISC, as well as decisions made during the design of processors. This chapter also talks about the background of C compilers, specifically GCC and its structure, with some comparison to the operation of LLVM.

2.1 Processor Design

There are many processor architectures to bear in mind when designing a processor. Many articles and studies have debated over which processor structure is the best, comparing speed to size on a chip to overall performance, like power and energy consumption, to rate these processor designs. One of the most common comparisons is done between the reduced instruction set computer (RISC) and the complex instruction set computer (CISC) architectures. This comparison will be talked about more in section [2.1.1](#). Even after deciding on a general instruction set architecture (ISA) to follow, there are many other decisions that go into the process of designing the processor, talked more about in section [2.1.2](#).

Hand-in-hand with processor design comes the compiler that allows code to be written to

and executed on the processor. GCC, which stands for “GNU Compiler Collection”, supports over 30 different processor architectures and 7 programming languages, and is one of the most used compilers for processor execution [11]. Another rising compiler is LLVM, which stands for low-level virtual machine. These compilers will be compared in section 2.2.4. The general design flow of a compiler will be talked about in section 2.2.1. Finally, GCC will be discussed in further detail in section 2.2.2, since GCC is the compiler used in this project.

2.1.1 RISC vs CISC

The debate of whether RISC or CISC is a higher performer in the playing field of computer and processor architectures is one that was sparked around the time of the mid-80s. The general consensus for a while was that the RISC architecture was the superior performer, but this was during a time when the main constraints were chip size and processor design complexity [12]. Nowadays, architect engineers are more concerned with the energy and power consumption of a processor, which largely changes the debate. Arguably, when comparing RISC and CISC architectures based on today’s more relevant constraints, it is irrelevant whether the processor is a RISC or a CISC. Rather, it is other components of the processor that aren’t categorized under the RISC/CISC ISA that make the processor execute more efficiently, with respect to its energy and power consumption [12, 13].

2.1.1.1 CISC

The idea of a reduced instruction set computer (RISC) came around to specifically compete with the presently (in the early 80s) used complex instruction set computer (CISC). CISC was the architecture currently used on nearly all computers and computing machines at the time. Some of the more common ones were the Intel x86 and Motorola 68000 [14]. Some basic characteristics that make a processor have a CISC architecture are:

- Large instructions sets: One of the goals of a CISC architecture is to cover many programming scenarios through complicated instructions
- Complex instructions: Some instructions are more complex than the basic add and subtract, and might contain multiple basic instructions in one.
- Instructions that operate over different numbers of clock cycles: Since there are so many instructions, many of them have different structures and take a different number of clock cycles to complete, which can make pipelining difficult [12, 14].
- Multiple addressing modes: CISC processors typically have a number of ways to reference memory locations.
- Register limitations: CISC architectures typically only have 16 registers, which is not always enough to support all functionality going on at one time. Often, values have to be transferred from registers into memory to make space so certain manipulations can be done. These values are then transferred back into the corresponding register when the manipulations are over. This can be a waste of time, as transferring data in and out of memory is not always a quick task [14].
- Multiple instruction formats: Some of the instructions will do their operations from register to register, some memory to register, and others memory to memory [14]. This can greatly affect the number of clock cycles it takes for the instruction to be executed.

To this day, CISC is largely used on most large-scale electronic devices with processors, such as laptops, desktop computers, and servers.

2.1.1.2 RISC

RISC was designed with the goal of simplifying the complicated instruction set known to the CISC architecture. Many of the CISC instructions were uneven and took too long to execute. RISC takes the burden of the complicated instructions off the architecture and places it in the compiler [15]. For a RISC processor, the compiler needs to be much heftier, being able to break down the same code that is executed by CISC processors into much more basic instructions that can execute on a RISC implementation. Studies on program behavior showed that 25% of instructions in CISC instruction sets make up 95% of the program execution time, meaning about 75% of the instruction set are hardly used or not used at all [14]. Studies such as these proved that a RISC architecture could be implemented realistically and would be quite useful in reducing chip size. Some characteristics of a RISC architecture are:

- Small instruction sets: Of course, a main goal of RISC was to reduce the instruction set from CISC. Usually RISC architectures only have about 20 instructions or less.
- Simple instructions: Instructions are stripped down to only the most basic operations, like add, subtract, shift, etc.
- Instructions all take the same number of clock cycles to execute: Instructions usually take 4-5 clock cycles, depending on the design, and all instructions take the same amount of time to execute, simplifying the pipelining process.
- Few addressing modes: Typically, RISC processors will only have direct addressing mode, register-direct addressing mode, and only maybe a couple others, such as PC-relative.
- Large number of registers: RISC processors usually have at least 32 general-purpose registers. Since the processor takes up less space on the chip, some of the extra space can be used for more registers [13].

Table 2.1: Characteristics of RISC vs. CISC

Architecture Characteristic	RISC	CISC
Instruction Set Size	small	large
Instruction Complexity	simple	complex
Instruction Execution Times	all the same	different
Number of Addressing Modes	few, 3-4	many
Number of Registers	at least 32	very few, generally only 16
Number of Instruction Formats	two: load-store, reg-reg	three: load-store, reg-reg, reg-mem, mem-mem

- One instruction format: RISC processors only have register-to-register instructions, with only the load and store instructions being capable of accessing memory.

Today, RISC processors are mostly used in smaller electronics, such as tablets, phones, and smart watches.

Table 2.1 displays the characteristics of RISC and CISC listed above in a way that makes them easy to compare.

The most basic RISC processor needs nothing more than an instruction execution unit, an arithmetic unit, memory, I/O peripherals, and a bus to connect all these units. A RISC processor can be extremely simple in structure, and still be able to run the same code as a CISC or more complex-structured processor [1]. Figure 2.1 represents a block diagram of the most simple RISC processor. When compared to Figure 3.8, it can be seen that the DMF RISC processor has a RISC architecture, but is not of the simplest design.

Figure 2.1: Basic RISC block diagram [1]

2.1.1.3 Comparison: Which is Better?

The question of which processor is better really depended on the time that question was asked. Back in the 80s and 90s, this question could be answered by which fit onto a smaller chip size and was still able to execute quickly. RISC programs were longer than CISC programs, but only by about 30% [14]. This is one of the few shortcomings of the RISC processor. Some of the more complex instructions in the CISC architecture took multiple instructions to replace the equivalent functionality in a RISC processor. Other than this, there were only good things when talking about switching to a RISC processor. Despite the slightly longer programs, however, studies have actually found that RISC execution is faster than CISC, largely because much of the run-time complexity is resolved at compile-time for the RISC processor [16].

So then, why are all processors not a RISC architecture? First, companies did not necessarily need to switch to a different processor to get a smaller chip size, until the phone and tablet age came about. Secondly, as technology advanced, the question was no longer of chip size, but rather the energy and power consumption. With these new variables in play, the processor architectures were re-compared, and found to be very similar. In fact, it was found that any performance gains were not due to characteristics that had to do with the RISC/CISC architecture, they were instead other design adjustments made to the processor architecture, such as cache memory, branch prediction, out-of-order execution, fetch prediction methods, along with other instruction organization methods [13, 17]. These added characteristics make the processor

“smarter”, as they allow it to predict what will happen next based on previous execution. When these methods are executed in a way that they are correct a high percentage of the time, this saves much processing power and execution time. These methods will be talked more about in section [2.1.2](#).

2.1.2 Design Decisions

When designing a processor, more goes into the decision process than just what ISA should be used. Things like memory architecture, I/O peripheral access, cache memory, and pipeline structure are just some of the basic decisions that need to be made. These are talked more about in Chapter 3. Some of the more interesting decisions come in when optimizing the processor. Aspects like branch prediction and out-of-order execution make the complexity of the processor much greater, but can also largely increase the performance.

2.1.2.1 Branch Prediction

Branch prediction is a method used to guess what the outcome of a conditional jump or branch statement will be. Referring to Figure [3.9](#), it can be seen that different stages of different instructions are executed at the same time. So, when a conditional jump or branch statement is brought into the instruction fetch phase, it will be another few clock cycles (2 in the case of the DMF RISC processor) before the processor knows if the jump will occur or not, since the outcome of the conditional is decided in the execute stage [\[18\]](#). To avoid the stalling of the pipeline that would normally have to take place until the conditional branch statement was in the execution phase, some processors implement branch predictors. When a branch predictor predicts correctly, some time is saved since the pipeline does not have to be stalled, and instructions continue executing as they would. If the prediction is incorrect, then the processor has to ignore the instructions that have been brought into the pipeline incorrectly, and carry on from where the next

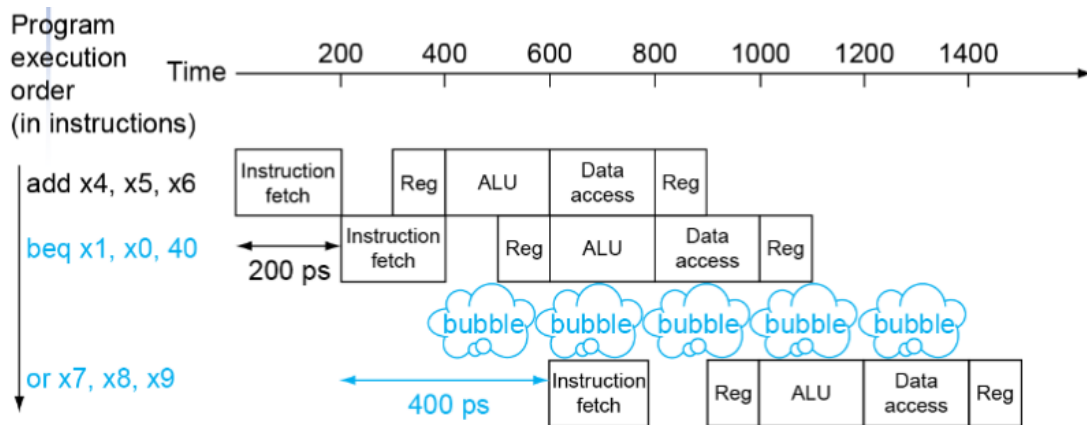

Figure 2.2: Pipeline with no branch prediction [2]

instruction will be. An incorrect branch prediction looks a lot like no branch prediction at all in terms of time it takes to execute in the pipeline. This can be seen by comparing Figures 2.2 and 2.3.

Often, a branch prediction can be as simple as one bit. If this bit is a 0, then it is predicting that the branch will be false. If the bit is a 1, it is predicting the branch will be true. Every time the bit predicts incorrectly, it changes to match what actually happened. In the case of loops, which is how most conditional branches are used, this can be a very effective method, as the branch predictor is usually only incorrect on the first and last iteration of the loop. Depending how many times the loop executes, having only two incorrect predictions can make for a very small percentage of wrong guesses. Since the worst case scenario is that upon a false prediction, the pipeline is delayed only as much as it would be without any branch prediction at all, having a branch predictor is only advantageous to the efficiency of the processor.

An interesting method some processors use to eliminate buffer time, even with a false branch prediction is having a small pipeline in parallel with the main pipeline. This small pipeline will start executing instructions starting where the processor thinks the branch will NOT bring the processor to. For example, if a branch predictor thinks the branch will not be executed, the

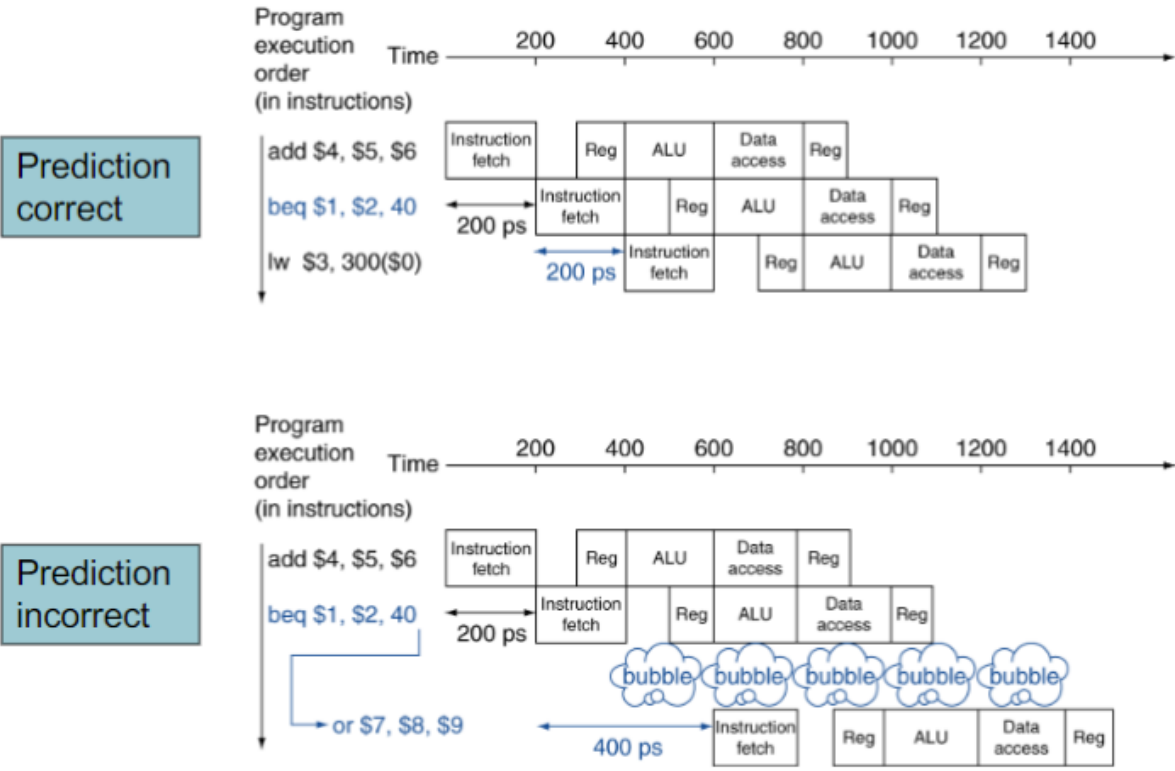

Figure 2.3: Pipeline with correct and incorrect branch prediction [2]

main pipeline will continue executing the instructions as usual, and the side pipeline will execute instructions starting from where the branch would bring the pipeline to if the condition for the branch was met. This way, even if the branch prediction is incorrect, those instructions have been being executed on the side all along, and the transition is much smoother, still with some delay, though [18].

2.1.2.2 Out-of-Order Execution

Out-of-order execution is a method used to maximize hardware usage in a processor. At any given point in a typical pipelined processor design, only one instruction will be in the execute phase. If this instruction is, for example, a load, store, data transfer, or flow control instruction, the ALU will not generally be used, and is sitting idle. Meanwhile, there may be other instructions that are manipulation instructions that will need to use the ALU. Out-of-order execution takes advantage of all hardware items at once, and orders instructions in a way that optimizes the use of hardware, rather than ordering them in the order they are written in the program memory. Out-of-order execution can be very effective in optimizing the processor, as seen from Figure 2.4 but can be a very complicated design component for a processor architect to take on.

2.1.2.3 Reducing Processor Size

Other options that were explored to reduce chip size of a processor were to move from 32-bit processors to 16-bit. This usually presents a problem because 16-bit processors would not have the same functionality and capabilities that a 32-bit would. At the 16-bit level, things like code size and instruction cache efficiency are greatly improved. On the other hand, however, due to the small bit size, 16-bit processors lack support for certain data types and three-address mode [19]. The problem with a processor not being able to handle a three-address mode is that a simple instruction, such as $r0 = r1 + r2$ has to be implemented using two instructions, a move

Figure 2.4: Performance of processors using out-of-order vs in-order execution [3]

and then an add: *mov r0,r1* followed by *add r0,r2* [19]. In [19], a process called move-folding is introduced to try and fix this problem to make 16-bit processors more appealing. The process of move folding is an interesting technique where an extra register (MR) is used to hold the value of the extra source register. When it comes time to execute, instead of selecting the destination register as the second source, the MR is used as the second source. This interesting solution could increase the chances of a 16-bit processor being more attractive than before, however there is still extra hardware used to properly implement this kind of instruction.

2.2 Compilers

The quality of a compiler can make a huge difference when designing code for an embedded system. Many compilers are used to decompose basic code languages, such as C, Java, or C++

Figure 2.5: Davidson Fraser Model [4]

Figure 2.6: Aho Ullman Model [4]

to run on CPUs. How efficient a compiler is can often be determined by how much they condense the code and the dynamic instruction count in the output executable file. Especially in embedded systems, these are indicators of power consumption and execution time [20]. Two main compilers used are GNU Compiler Collection (GCC) and Low Level Virtual Machine (LLVM). These are both often used to compile C code to standard RISC-V or ARM processors, and are often compared using bench-marking programs to determine their abilities to create short code and optimize different aspects like register allocation and dynamic instruction count.

2.2.1 Compiler Design

Compiler's have three main parts to them: a front end, a middle end, and a back end. Many compilers typically do the same general functions in each phase, but how they go about it differs for each compiler. Two main models of compilers are the Davidson Fraser Model, shown in Figure 2.5, which GCC is modeled off of, and the Aho Ullman Model, shown in Figure 2.6, which LLVM is modeled off of [21].

Generally, the front-end of a compiler parses the program and checks for syntax errors and

convert the file into some intermediate representation file format [5]. For Davidson Fraser, this file format is register transfer language (RTL), whereas the Aho Ullman Model uses an intermediate representation specific to the compiler. The middle-end is responsible for most of the optimization. This portion is where a compiler can shine, with the right optimization techniques. Typically, how well a compiler optimizes is based on how well it can condense the code and order the instructions in a way that makes the output as short and as quickly executed as possible. Usually, this portion can be done target-independently. The back end is essentially the code generator, and is responsible for converting the code from the optimized intermediate representation (or the RTL) to the binary the target processor will accept to create the executable. Sometimes, some optimization is left to the back end, depending on the target. Since GCC is the compiler used in this project, and it is based on the Davidson Fraser Model, this will be the model most closely discussed in the rest of this paper.

2.2.2 GCC

Launched in 1984 by Richard Stallman, the GNU Compiler Collection is a portable compiler designed to optimize and compile code for a wide array of processor targets [11]. GCC is one of the most widely used compilers for C and supports more processor architectures, and offers some coder-friendly features making any code compiled by GCC very portable [22]. GCC is compatible with multiple languages in the front end, and uses a common language-independent middle end and back end to compile code into target-specific machine code. No other compiler suite can do quite what GCC can, all while being free, open-source software [23]. Being older than LLVM, the optimization process has been worked on for longer, and is much more efficient and better at its process. An overall block diagram and more specific compilation overview can be seen in Figures 2.7 and 2.8, respectively. The next subsections will break down the three stages of the GCC compilation process: front end, middle end, and back end.

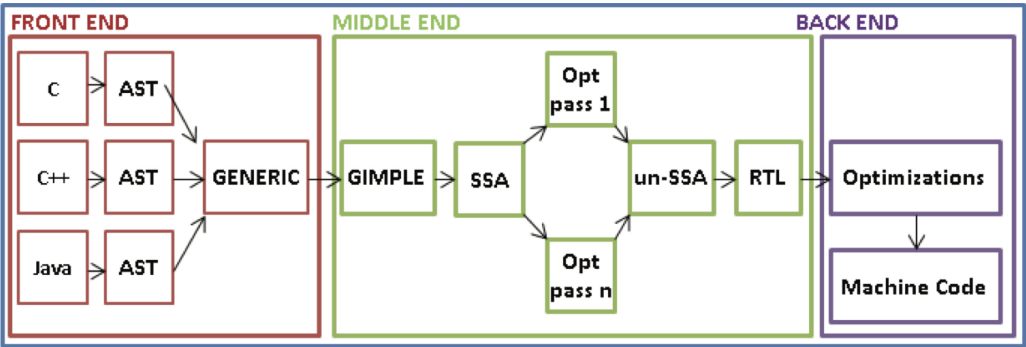

Figure 2.7: GCC compilation process block diagram [5]

Figure 2.8: GCC compiler overview [6]

2.2.2.1 Front End

As mentioned previously, the front end of any compiler is responsible first for checking for any syntactical errors in the code. The GCC front end specifically will then create the Intermediate Representation (IR) of the code in a tree-like format. The IR is language-independent, and convert many different languages into IR, such as Java, C, C++, and FORTRAN [5]. The tree structure the IR takes the form of is called GENERIC. GENERIC is the language the code is in when it goes from the front end stage of compilation to the middle end stage of the process, as seen in Figures 2.7 and 2.8. Since GENERIC is language-independent, the compiler process used for the middle end can be more universal, used for any language.

2.2.2.2 Middle End (Optimization)

The middle end is responsible for the first part of optimizing code to reduce execution time and output program size. The GENERIC trees are converted to GIMPLE, another language independent IR. In the transformation from GENERIC to GIMPLE, complicated processes and instructions are broken down into simpler statements [5]. This transformation process is called *gimplification*. After the gimplification process, Static Single Assignment (SSA) information is given to GIMPLE to incorporate the data flow. As seen in Figure 2.7, a series of optimization passes are then performed on the GIMPLE with SSA. The SSA is then removed and this is converted into Register Transfer Language (RTL). RTL is the language the middle end finishes in and passes along to the back end [5].

2.2.2.3 Back End

The back end converts the inputted RTL into machine language that is target-dependent. Different target-dependent optimizations can be done to reduce code size and execution time even

more. These optimizations include processes such as instruction scheduling and register allocation. Instruction scheduling reorganizes the instruction stream, only if the target processor has pipeline units [24]. It often attempts to reorganize in a way that causes as few dependencies as possible while still having the correct program results. The register allocator must take the pseudo registers in the RTL and map them each to an actual register in the target processor. Registers are an invaluable and high speed portion of the processor, so register allocation can be considered one of the most important optimization processes in the entire compilation [25]. There are two types of register allocation, intraprocedural and interprocedural. Intraprocedural allocates registers within a procedure, making sure there are enough registers, and making intelligent decisions about how to rearrange when there are not. Interprocedural allocates registers across multiple procedures. This mostly takes care of global variables, keeping them in registers permanently throughout program execution [25]. Of course, after these optimizations are complete, the machine code is generated to be run on the target machine or CPU.

Since the back end is responsible for generating the target-dependent machine code from the given RTL, the back end of GCC is where most processor architects would also retarget GCC to port the compilation process to their individual processor. The retargeting process is not a simple one, but GCC makes it very doable by being open-source. After understanding certain target processor components, such as the register file, pipeline, and ISA, the architect must redefine GCC's application binary interface (ABI) [21]. The ABI contains information regarding alignment of data types as well as defining how the stack will be used in a call, how registers will be used and data transferred, etc. The third step is to define and write three machine description files that will tell GCC about the processor's environment and setup [21]. The fact that very little GCC back end code needs to be altered to retarget the entire compilation process to a new target platform makes GCC very attractive for retargeting purposes.

Figure 2.9: LLVM architecture [7]

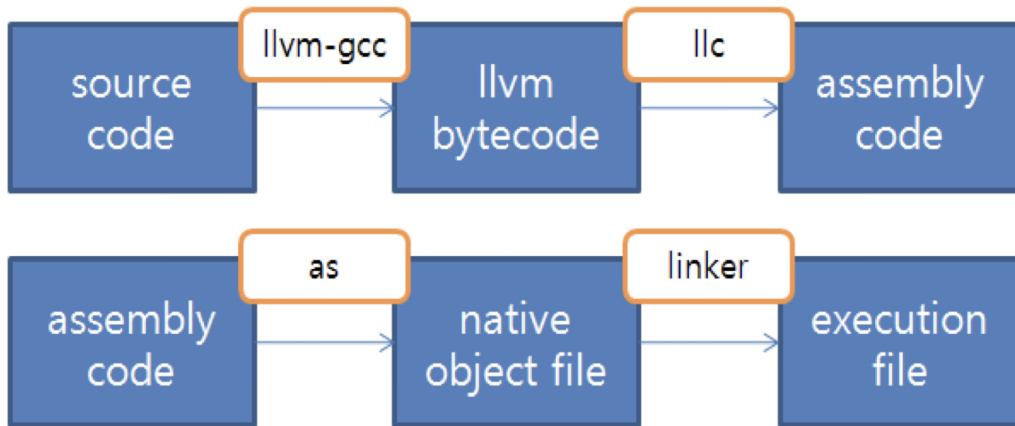

Figure 2.10: LLVM compilation process block diagram [8]

2.2.3 LLVM

Low Level Virtual Machine (LLVM) was created in 2003 by Chris Lattner for a Master's Thesis [7]. LLVM is largely based around optimizing during compile-time, link-time, and run time [8]. Unlike GCC, which compiles into an IR to optimize, and then overlays SSA, LLVM compiles directly to an IR that is in SSA form to perform optimizations. LLVM's architecture can be found in Figure 2.9. The LLVM compilation process can be broken down into a block diagram, as shown in Figure 2.10.

The LLVM compilation process starts with source code that goes through `llvm-gcc`. `llvm-gcc` is a front end compatible with C code based of GCC. It compiles C programs into LLVM bytecode, which is usually an object or executable file [8]. Next, the LLVM bytecode goes through `llc`,

Table 2.2: GCC vs LLVM Compiler Characteristics

Characteristic	GCC	LLVM
Compiler Model	Davison-Frasser	Aho Ullman
Machine Description	RTL	SSA IR
Main optimization points	instruction scheduling and register allocation during back end	link-time
Register Allocation	Inter and intra (local and global)	Linear scan

which compiles the bitcode into assembly of the host machine, or another machine if specified. This is then assembled into the native object file, which is put through the `llvm` linker, which can merge multiple `llvm` bitcodes stemming from multiple C files into one execution file. The linker also provides most of the optimizations performed in the LLVM compilation process.

2.2.4 GCC vs. LLVM

GCC and LLVM have been comparing using many different variables and benchmarking programs. Table 2.2 compares some of the basic compiler features between GCC and LLVM.

It was found in most results that GCC is overall a better compiler due to its robustness and better optimization techniques. There are, however, pluses and minuses to both. In the end, however, code size determines memory length, and memory is the most expensive unit in a CPU, so whichever compiler makes the shortest programs takes the cake [20]. In a study done to compare GCC and LLVM on the EISC Processor, it was found that although LLVM was good with calculation intensive programs, GCC had the leg up on register allocation and jump optimization. As mentioned previously, register allocation can be one of the most crucial optimizations for shortening execution time of a program [20]. LLVM was able to get through calculation intensive functions due to its superior loop-unrolling techniques. LLVM is known to aggressively unroll

loops, which can end up shortening programs quite a bit. The GCC compiler, however, uses registers more often and more efficiently, and rearranges blocks in order to eliminate unconditional jumps, a factor that sets the bar pretty high for competitor optimizers [20]. In another study done to compare LLVM and GCC on an ARM Platform, it was found that while LLVM falls close to GCC in some benchmarks, in others it pales greatly in comparison. Specifically, code with heavy memory access was handled inefficiently by LLVM [8]. However, it was deemed that since most programs have many files and many function calls, and LLVM has a strong suit in linker optimization, LLVM's performance with these types of programs would shine, and be nearly equivalent to GCC [8].

Chapter 3

Custom 32-bit RISC Processor Design

This chapter discusses the design and relevant aspects of the 32-bit processor, including why certain design choices were made, and what alternatives were available.

3.1 Instruction Set Architecture

The instruction set architecture (ISA) of a processor is key to its design. The ISA contains information regarding how many bits the processor will be, the number of general purpose registers, the load-store technique, memory structure, input/output peripheral structure, addressing modes, and more. Most of the general functionality of the processor is defined in the ISA. For the DMF RISC processor, the processor is 32 bits to make it easier to match up with C compiled code. This means that each register will be 32 bits long, and memory would be capable of containing 2^{32} memory locations, more than enough, even if a Von Neumann memory architecture was chosen.

3.1.1 Register File

The register file contains the set of all registers used in this design. There are 32 general purpose registers, each of them capable of storing numbers up to 32 bits, which is the equivalent of a float in C. Other important registers include the status register, the stack pointer register, and the program counter. The status register is a 32-bit register where only 4 bits are used to keep track of the carry, negative, overflow, and zero (CNVZ) bits from any computation done by the processor. The status register is critical in making a decision for conditional jumps. The layout of the status register can be seen in Figure 3.1.

Figure 3.1: Status Register Bits

The status register bits (CNVZ) can be explained as follows:

- **C:** C is the carry bit. This bit is set to 1 when an executed manipulation instruction has a high carry out. This mostly applies for addition and rotate instructions. This bit is otherwise a 0.
- **N:** N is the negative bit. If any manipulation instruction results in a negative number (1 in the most significant bit place), this bit will be set to 1. Otherwise this bit will remain at 0.
- **V:** V is the overflow bit. If a manipulation instruction has operands that lead to a result that is too large to fit in a 32-bit register, the overflow bit will be set to 1. Otherwise this bit will remain at 0.
- **Z:** Z is the zero bit. If a manipulation instruction results in zero, this bit will be set to 1. Otherwise this bit will remain at 0.

Figure 3.2: Program Counter Register

The program counter is important for keeping track of which address in memory holds the next instruction to be executed. The program counter (PC) needs to have enough bits to contain every possible address in the program memory, usually the ROM (read-only memory). Since this processor is 32-bits, the PC is 32 bits long, and can therefore point to 2^{32} memory locations, if needed. The layout of the program counter register can be seen in Figure 3.2.

Lastly, the stack pointer is a register used to keep track of what spot in the stack the processor will use to store information in next. In this processor, the stack is mostly used to store information, such as the SR and the PC, for maintaining the state of the processor when returning from a call. When items are added to the stack, the stack pointer will decrement to point to the next location in stack. The stack pointer in this processor starts at the top and stores in decreasing address orders. This does not change the standard behavior of the stack, where items are pushed and popped into and out of stack. Like most stacks, the stack is also still last in first out, or LIFO. The layout of the stack pointer register can be found in Figure 3.3.

Figure 3.3: Stack Pointer Register

3.1.2 Peripheral Layout/Stack Design

For the DMF RISC processor, the peripherals are memory mapped, meaning that the peripherals are accessed by using a designated spot in the data memory RAM. The alternative to memory-mapped peripherals is separate-mapped peripherals, which are accessed via a memory block that

is separate from the data memory. In this memory-mapped peripheral design, the stack is treated as a peripheral. Since the stack is only used for storing the PC and SR during a call-return sequence, not much space needs to be designated to stack. From memory spaces 0x3ff0 to 0x3fff are designated to the stack and other peripheral uses.

3.1.3 Memory Architecture

Two main memory architectures that are commonly used in processors are Harvard and Von Neumann. Von Neumann is a structure where the program and data memory both share one block of memory. Typically, the data memory will start at address 0 (or some other arbitrary address value) and fill upwards, while the program memory will start at the last address and fill down.

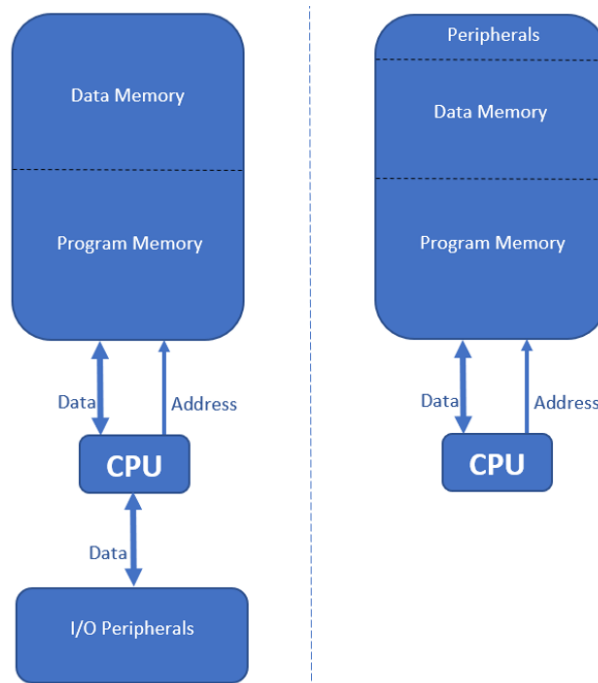

Figure 3.4: Von Neumann memory structure with separate-mapped (left) vs. memory-mapped (right) I/O peripherals

For this processor, the Harvard memory architecture was implemented. This means that a different memory block was used for the program memory and the data memory [26]. For the DMF RISC processor, a read-only memory (ROM) block was used for the program memory, since the program memory is never written to after the initial programming. A random-access memory (RAM) block was used for the data memory, where the peripherals and stack are also located. The memory and stack layout of this processor can be seen in Figure 3.5.

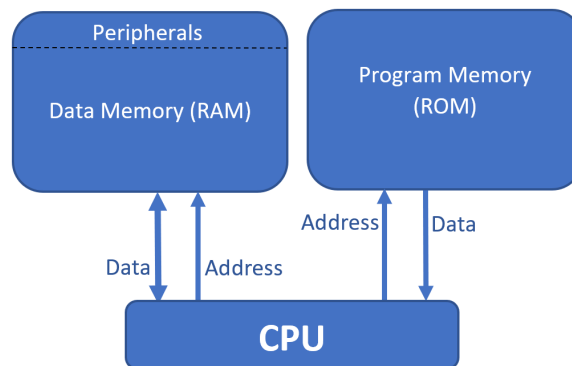

Figure 3.5: Harvard memory structure with memory-mapped I/O peripherals

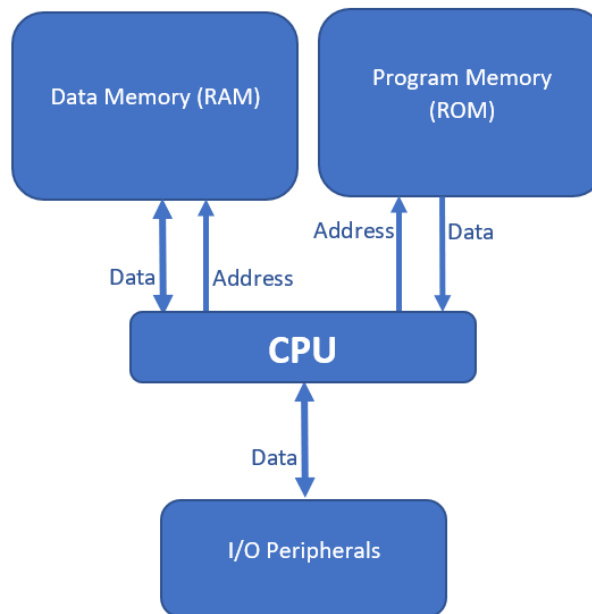

Figure 3.6: Harvard memory structure with separate-mapped I/O peripherals

3.1.4 Addressing Modes

Addressing modes allow the program writer to reference addresses in memory in different methods. Available in the DMF RISC is direct addressing mode, PC-relative addressing mode, and register direct addressing mode using the general purpose registers. The program can also use the SP as the address. How these addressing modes are implemented is talked about later, in section [3.3.1](#), specifically the load and store subsection. Figure [3.7](#) also visually explains the different forms of addressing modes used in most basic RISC processors.

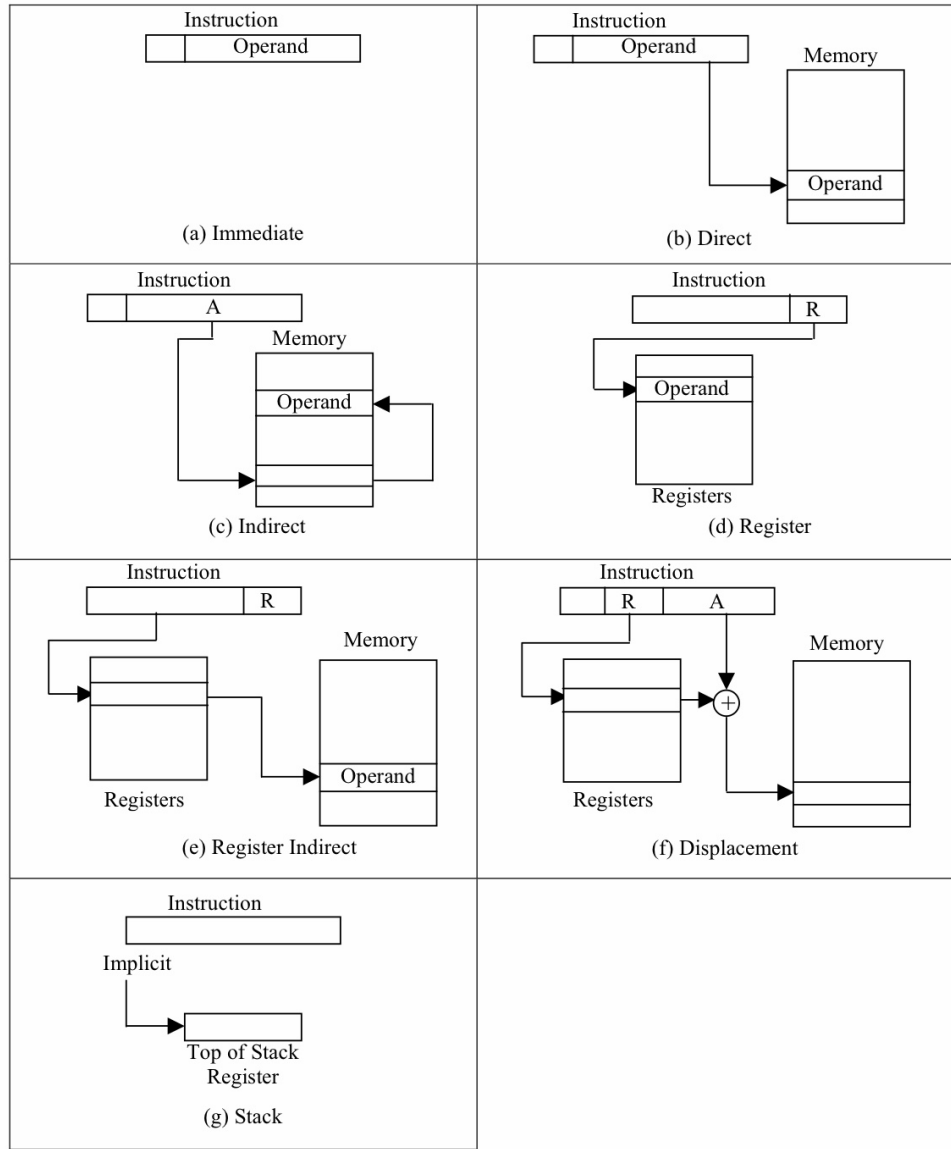

Figure 3.7: Addressing mode types [9]

3.2 Hardware Implementation

There are many functional pieces that make up the hardware implementation of the DMF RISC processor designed for this project. The DMF RISC processor was designed using Verilog hard-

ware description language (HDL) at the register transfer level (RTL). Some features of the hardware implementation are the four-stage pipeline, the arithmetic logic unit (ALU), the shifter, the multiplier/divider unit, the register file, the cache memories, as well as the main memories (program and data), and the phase-locked loop (PLL) clock generator (not pictured in Figure 3.8).

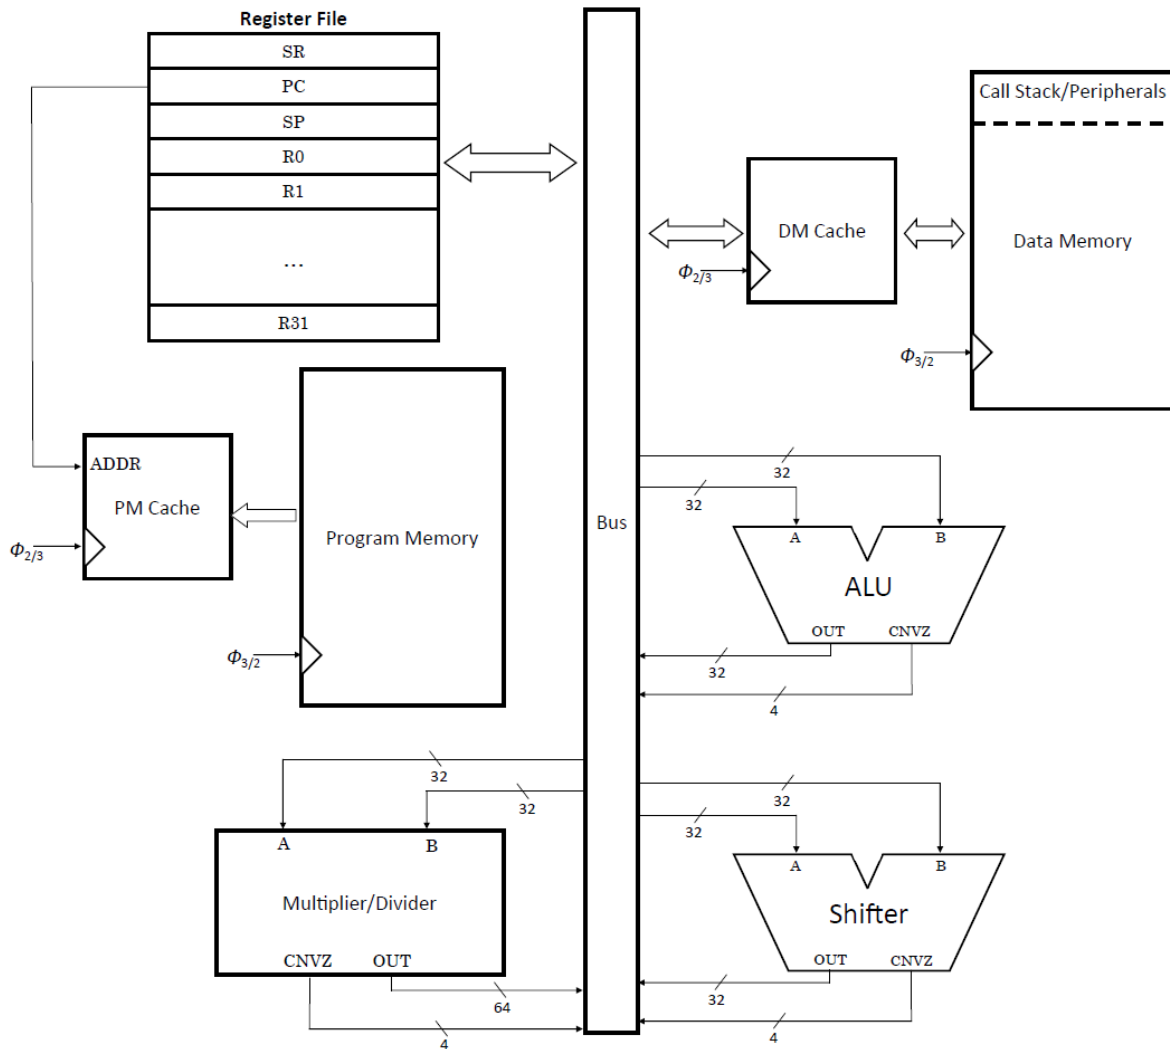

Figure 3.8: DMF RISC CPU Functional Block Diagram

Pipeline Stage	Pipeline						
IF	I_0	I_1	I_2	I_3	I_4	I_5	...
OF		I_0	I_1	I_2	I_3	I_4	...
EX			I_0	I_1	I_2	I_3	...
WB				I_0	I_1	I_2	...
Clock Cycle	1	2	3	4	5	6	...

Figure 3.9: Four-Stage Pipeline [4]

Figure 3.10: Four-Stage Pipeline Block Diagram[4]

3.2.1 Pipeline Design

The use of a pipeline is key for increasing the throughput rate of instructions being executed in a CPU [27]. The four-stage pipeline in the DMF RISC Processor consists of the following four stages: instruction fetch, operand fetch, instruction execution, and write-back. After the first instruction is finished with the instruction fetch stage, the next instruction may enter the pipeline, and so on. In the CPU implementation, it's important to note the order that the instructions are executed during any single clock cycle. Looking at Figure 3.9, if the processor is in clock cycle 4, there is an instruction in each of the pipeline stages. For the purpose of fixing any dependency issues, the write-back stage with instruction I_0 will be executed first, then the execution with I_1 , then the operand fetch with I_2 and finally, the instruction fetch with I_3 . The implications of dependencies will be talked about more later in section 3.2.1.2.

3.2.1.1 Instruction Fetch

The instruction fetch (IF) stage is fairly straightforward. This stage consists of loading the next instruction word from the program memory cache and transferring it into internal registers in

the main CPU. The instruction word is generally broken up into the op-code and other relevant pieces of the instruction word, such as operand values. The program counter is then incremented to point to the next instruction word. The instruction fetch stage is also responsible for stalling the processor if the next instruction will be a jump, call, return, load, or store. Any instruction requiring a change in program counter or a second instruction word requires some processor stalling to execute properly.

3.2.1.2 Operand Fetch

The operand fetch (OF) stage largely depends on the type of instruction being looked at. For manipulation instructions, the original instruction word had two operands, two source registers, and a destination register that the result is stored in. This data must be used to find which general purpose registers are being used in this instruction, and obtain the data from within these registers. The OF stage is also responsible for working out all dependency issues. In pipelining, multiple dependency issues can be encountered, such as read after write (RAW), write after read (WAR), and write after write (WAW). The one that is focused on being handled in this pipeline structure is read after write. If two consecutive instructions use the same operand as the destination operand, it is critical that the value from the first instruction be placed in the operand before the next instruction is executed. To solve this problem, a technique called data forwarding is called. The operand fetch stage is responsible for executing all data forwarding. Data forwarding is the process of using internal registers to transfer the value of an operand after an instruction is executed to the next instruction for execution with the proper number values. For example, if an instruction that is the equivalent of $R2 = R2 + R1$ is followed by an instruction that uses the value of R2 to multiply with R3, data forwarding will be needed because while the addition instruction is in the execution phase, the multiplication instruction will be in the operand fetch stage, where the values of the registers will be obtained. In this case, when the

multiplication instruction is in the OF stage, instead of obtaining the value of R2 by looking in the register file, the processor will use the result of the addition instruction as the value of R2. Because there are many cases that could occur that would require data forwarding, the OF stage is one of the most logic-heavy stages, with many conditional statements to make sure all bases are covered.

3.2.1.3 Instruction Execution

Instruction execution (EX) is exactly what it sounds like, the actual execution of the instruction. If the instruction is a manipulation instruction, the ALU, shifter, or multiplier/divider is used to perform logic on the operands and store the result in an internal register. If the instruction is a load or store, in this phase, the data will be stored to or loaded from memory. If the instruction is a jump, call, or return, during this stage, the program counter will be set to the new location for it to continue keeping track of instruction words in the program memory.

3.2.1.4 Write Back

In the write back phase, the result of the instruction execution is written back into the general purpose destination register, if this applies. If the instruction was a flow control instruction, such as a jump, call, or return, this phase will also be responsible for telling the processor there is no longer a need to stall.

3.2.2 Cache Memory

Cache memory is an important feature when a processor would otherwise be reading/writing from large, monolithic blocks of memory. In hardware, the blocks of memory being used for program and data memory can be very large and far away from the CPU, making interactions with these blocks take a long time. To solve this issue, often cache memories will be used. A

cache memory is a smaller block of memory that temporarily stores relevant blocks of memory to be used with the CPU. It is up to the architect to decide what makes a block of memory relevant, and how much memory will be placed in cache at a time. For the DMF RISC processor, the cache memories each contain 8 blocks of memory, where each block has 16 words.

The way this processor decides which blocks of memory are placed in cache (placement strategy) are simply based on which addresses are used by the CPU. When an address is called for by the CPU, the corresponding block will be moved into cache so the CPU can access that address. Once the cache is full, a replacement strategy must be implemented to decide which blocks will be overwritten to accommodate for the new block needed by the CPU. In this processor, the replacement strategy is the block of memory that was used the longest time ago is the one that will be replaced by the new block of memory.

There are a few ways to map the main memory blocks to blocks in cache.

- Associative: For a cache that is fully associative, any block in memory can be placed anywhere in the cache. This means for a replacement strategy, all blocks in cache will have to be compared to see which was the least recently used. A visual of this cache organization can be seen in [Figure 3.11](#).

Figure 3.11: Fully associative cache organization[10]

- **Direct:** For a cache that is direct mapped, each block in main memory has a designated block in cache, depending on the group bits in the address. Each address in main memory is broken into parts that help for organizing where each block belongs. This organization is broken down in a visual in Figure 3.12.

Figure 3.12: Direct-mapped cache organization[10]

- **Block-set Associative:** Block-set associative can have any number of blocks, for example 4-way set associative or 2-way set associative. This organization method is in between fully associative and direct mapped. Instead of only having one spot each memory block can map to, like in direct-mapped, there are a set number of spots each block in memory can map to. If the organization is 2-way set associative, like in Figure 3.13, there are 2 spots in cache each block in main memory will be able to map to.

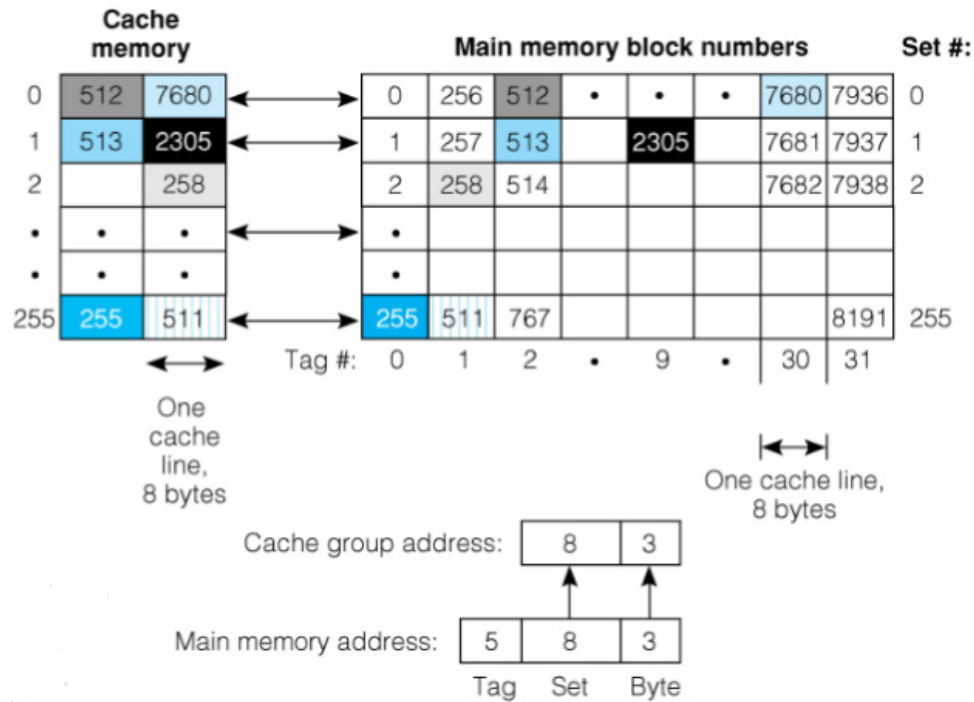

Figure 3.13: 2-way set associative cache organization[10]

Using an organization technique like direct-mapped or block-set associative makes it easier to decide which blocks to replace when the cache is full. Sometimes, however, using these methods makes no sense. For example, in the case of a program memory where the addresses will usually be called chronologically, it might make more sense to use fully associative rather than direct-mapped or block-set associative since the latter two will restrict how many relevant blocks of program memory will be able to be in cache at a time. The DMF RISC Processor uses 2-way set associative to map the main memories to the cache.

There are some general properties that can be used to decide on an effective replacement strategy for cache memory. These include temporal and spacial locality. Temporal locality is a property of most programs where if a specific address in the memory is used by the CPU, it will most likely be used again in the near future. Furthermore, spacial locality is a property that if an

address in memory is used by the CPU, it is likely that addresses nearby will also be used in the near future. This is especially true for the program memory, where generally, the addresses are needed in chronological order, with the exception of the case of a jump, call, or return.

Once it has been decided that a block in cache will be replaced, it is also important to keep track of if this block of memory needs to be written back to the main memory or not. If while in the cache, a block of memory is at all written to, a write-back of that block will need to be done to ensure that the main memory reflects the new state of that block of memory. It is important to note that some memory blocks that do not have a write enable, like ROM, will not require a write-back. This is true for program memory, in particular.

In the DMF RISC Processor, there are two cache memories, one for the data memory, and one for the program memory. Since the memory structure was Harvard and then DM and PM were separated, this was necessary. This can be seen in Figure 3.8.

3.2.3 Stalling

Stalling is required during any flow control instructions, such as jump, call, and return, as well as for load and store, which use a second instruction word as the address in data memory being accessed. The stalling is required for different reasons for each of these cases. For the flow control instructions, stalling is required because until the program counter is set to the new address, there is no way to get the next instructions to execute. For the load and store, stalling is implemented for only one clock cycle so that the instruction work with the memory address isn't implemented as an actual instruction. Additionally, because the data memory is being accessed, often a clock cycle is needed to get the information from the data memory.

Figure 3.14: Clock Phases

3.2.4 Clock Phases

For the best efficiency, a PLL is used to generate three clocks with phases 30° phase shifts. The ϕ_1 clock was used as the CPU clock. The other two, ϕ_2 and ϕ_3 were used as the cache/main memory clocks. Which clock was used for which memory block depended on if the main memory was writing to cache or if cache was writing back to main memory. This clock layout made for the most efficient memory-CPU execution.

3.3 Instruction Details

This section details the implementation of the different instruction types.

3.3.1 Load and Store

Load and store instructions are used to transfer data in and out of memory to general purpose registers. The load/store operations require two instruction words. The first instruction word (IW0) contains the opcode and an R_d , R_i , and R_j field. The R_i field is used to determine the addressing mode of the instruction, the R_d field is used to tell the processor which general purpose register to load into, and the R_j field is used to tell the processor which general purpose register

to store from. The second instruction word (IW1) contains the address offset the CPU will use to load or store. The instruction word breakdowns can be found in Figure 3.15.

Figure 3.15: Load and Store IW0 (top) and IW1 (bottom)

The addressing mode used depends on the value in the R_i field. The possible addressing modes to be used are absolute, PC relative, SP, and register direct. A description of each of these and their corresponding R_i field value can be found in Table 3.1.

Table 3.1: Addressing Mode Descriptions

Mode	R_i	Effective Address Value
Absolute	0	The value in the address field
PC Relative	1	The value of the PC register + the value in the address field
SP	2	The value of the stack pointer (SP) register
Register Direct	3-31	The value of the R_i register operand

Table 3.2: Load and Store Instruction Details[4]

Instruction	Mnemonic	Opcode	Function
Load	LD	0x15	Load value from memory at the effective address or I/O peripheral into the R_d register
Store	ST	0x16	Store the value in the R_j register into memory at the effective address or I/O peripheral

3.3.2 Data Transfer

Data transfer instructions are the swap and copy instructions. These only require one instruction word since they do not have an address offset. The swap and copy instructions solely deal with register to register interaction. Swap swaps the values in two registers, while copy copies the value from one register into another. The instruction word layout and instruction descriptions can be seen in Figure 3.16 and Table 3.3, respectively.

Figure 3.16: Data Transfer Instruction Word

Table 3.3: Data Transfer Instruction Details[4]

Instruction	Mnemonic	Opcode	Function
Copy	CPY	0x17	Copy the value from the R_i register into the R_d register
Swap	SWP	0x18	Swap the values in the R_d and R_i registers

3.3.3 Flow Control

Flow control instructions include all jumps, conditional and unconditional, as well as call and return. The distinct difference between a jump and a call is that a jump can not be returned from, whereas a call can. This is because during a call, the SR and PC are stored in stack so that upon return the values can be retrieved from the stack and stored back into their respective registers. For all of these, two instruction words are required, again an IW0 with the op-code and addressing mode (and for a jump, conditional information), and an IW1 with the address offset. The last 4 bits, C, N, V, Z, are all used to tell the condition of the jump. For a call and return, these field values are ignored or left as 0s, since only the opcode and IW1 are needed for the call and return instructions. The instruction word layouts can be found in Figure 3.17.

Figure 3.17: Flow Control IW0 (top) and IW1 (bottom)

For conditional jumps, the status register is checked to see if the corresponding bit meets the requirement for the jump before the jump is executed. This means sometimes there is a stall in the CPU and then no jump is made because the condition fails. There are methods that can be used to predict if the jump will fail or not, however these were not used in the DMF RISC Processor. The conditional and unconditional jump descriptions can be found in Table 3.4.

Table 3.4: Jump Condition Code Description[4]

C	N	V	Z	Mnemonic	Description
0	0	0	0	JMP / JU	Jump unconditionally
1	0	0	0	JC	Jump if carry
0	1	0	0	JN	Jump if negative
0	0	1	0	JV	Jump if overflow
0	0	0	1	JZ	Jump if zero / equal
0	1	1	1	JNC	Jump if not carry
1	0	1	1	JNN	Jump if not negative
1	1	0	1	JNV	Jump if not overflow
1	1	1	0	JNZ	Jump if not zero / not equal

Table 3.5: Flow Control Instruction Details[4]

Instruction	Mnemonic	Opcode	Function
Jump	JMP	0x19	Conditionally (or unconditionally) set the PC to the effective address
Call	CALL	0x1A	Write the PC followed by the SR onto the call stack, set the PC to the effective address
Return	RET	0x1B	Read the top of call stack into the SR, then read the next value into the PC

3.3.4 Manipulation Instructions

Manipulation instructions are some of the more basic instructions that manipulate the contents of registers. These include adding, subtracting, multiplying, and dividing, as well a logical manipulation, such as AND, OR, XOR, and NOT. These instructions all take R_i and R_j fields and use the contents in the corresponding registers to perform the manipulation. The R_d register is

the destination register because the result of the manipulation gets stored in this register. The R_i and R_j registers are referred to as the source registers. In some cases, like the multiply and divide instructions, the R_i register contents will also be replaced by results of the manipulation instruction.

Figure 3.18: Manipulation Instruction Instruction Word

Table 3.6: Manipulation Instruction Details

Instruction	Mnemonic	Opcode	Function
Add	ADD	0x1	Store $R_i + R_j$ in R_d
Subtract	SUB	0x2	Store $R_i - R_j$ in R_d
Add constant	ADDC	0x3	Store $R_i + R_j$ in R_d , where R_j is a constant
Subtract constant	SUBC	0x4	Store $R_i - R_j$ in R_d , where R_j is a constant
Multiply	MUL	0x8	Store the most significant half of $R_i \times R_j$ in R_i and the least significant half R_d
Divide	DIV	0x9	Store the quotient of R_i / R_j in R_d and the remainder in R_i
Exclusive OR	XOR	0xA	Store $R_i \oplus R_j$ in R_d
Invert	NOT	0x11	Store $\sim R_i$ in R_d , ignores R_j field
AND	AND	0x13	Store $R_i \bullet R_j$ in R_d
OR	OR	0x14	Store $R_i \text{ OR } R_j$ in R_d

3.3.4.1 Shift and Rotate

Last, the shift and rotate instructions are used to shift and rotate values in registers a certain number of times. For these instructions, the value in the R_i register is the one shifted or rotated, and then stored in the R_d register

. The number of times the value is shifted or rotated is dependent on the value in the R_j field. In the DMF RISC Processor, the value will not shift more than 4 times to the right or left.

Table 3.7: Shift and Rotate Instruction Details

Instruction	Mnemonic	Opcode	Function
Shift right logical	SHRL	0xB	Shift R_i right logically by R_j bits and store in R_d
Shift right arithmetic	SHRA	0x12	Shift R_i right arithmetically by R_j bits and store in R_d
Rotate right	ROTR	0x5	Rotate R_i right by R_j bits and store in R_d
Rotate left	ROTL	0xC	Rotate R_i left by R_j bits and store in R_d
Rotate left through negative	RLN	0xD	Rotate R_i left through negative bit in SR by R_j bits and store in R_d
Rotate left through zero	RLZ	0xE	Rotate R_i left through zero bit in SR by R_j bits and store in R_d
Rotate right through negative	RRN	0xF	Rotate R_i right through negative bit in SR by R_j bits and store in R_d
Rotate right through zero	RRZ	0x10	Rotate R_i right through zero bit in SR by R_j bits and store in R_d

Chapter 4

GCC Back End Alterations

This chapter discusses what changes were made to the back end of GCC with respect to the OR1k files to match the opcodes of the DMF RISC processor.

4.1 OR1k Structure

The Open RISC 1000 Processor (OR1k) is supported by the GCC C compiler. This means there are a collection of files that can be used in the back end of GCC to port the intermediate language or RTL to be compatible binary machine code with the processor. The OR1k is the closest processor to the DMF RISC Processor, so it is the only one that could be used with some basic opcode manipulation.

4.1.1 General Structure

The OR1k is somewhat complicated in its instruction set as it has its instructions divided by addressing mode. Some instructions that have an immediate addressing mode (where a constant is used in the manipulation), have a standard 6-bit op code followed by a destination and source

register and then the 16-bit constant value. This, however, is not how all instructions work. Other instructions that use register-register for manipulation have a general 6-bit opcode in the beginning, the three registers (5-bits each, destination, A, and B), followed by some unused bits and then 4-5 bits of a specific opcode at the end of the instruction word. This differs from the DMF RISC processor majorly, and causes some misalignment when trying to match the OR1k instruction words to the DMF RISC processor's.

4.1.2 Alterations made to OR1K Back End

The alterations made to the OR1k filed in the back end of GCC were simply the changing of the opcode values.

4.2 GCC Back End

GCC's back end is used for porting the IR to the machine code compatible with a specific processor. By default, this processor is the machine the code is being compiled and run on, but other processor architectures can be chosen, like in this case, the OR1k processor.

4.2.1 Altered Files

The files that needed to be altered to create machine code that is compatible with the DMF RISC Processor were limited to the OR1k files. In the file path `../toolchain/binutils/opcodes`, there are a list of 8 files that coincide with creating the machine code for an OR1k processor, specifically. The files are:

- `or1k-asm.c`
- `or1k-desc.c` : tables of opcode output values

- or1k-desc.h : contains actual opcode values, as well as other opcode relevant enumerations (enums) used in or1k-desc.c
- or1k-dis.c
- or1k-ibld.c
- or1k-opc.c : contains some opcode structures, and also how the instructions will be printed in the disassembly file
- or1k-opc.h : contains some enums that are used in or1k-opc.c
- or1k-opinst.c

The main file that was edited was the or1k-opc.c since it contained the opcode values that needed to be altered. These specific opcodes were hard-coded into their shifted bit positions in an enum table, as can be seen in Figure 4.1. The last line of code in these blocks includes a hex number that is 8 digits long (or 32 bits, the length of one instruction word). The most significant six bits of these hex numbers are the opcode for the corresponding instruction. For example, the opcode of the immediate add instruction for the OR1k processor is 0x27, or decimal 39. Since this opcode needs to be in the most significant 6 bits, however, this is shifted up and the bits go from least significant spaces to most significant spaces, as can be seen in Figure 4.3. Since in the DMF RISC processor the opcode for an immediate add instruction is simply 0x03, this shifted to the left twice would be 0x0C, as seen in Figure 4.2.

```
/* l.addi $rD,$rA,$simm16 */
{
  { 0, 0, 0, 0 },
  { { MNEM, ' ', OP (RD), ' ', OP (RA), ' ', OP (SIMM16), 0 } },
  & ifmt_l_lwz, { 0x9c000000 }
},
```

Figure 4.1: or1k-opc.c before changes

```

/* l.addi $rD,$rA,$sim16 */
{
  { 0, 0, 0, 0 },
  { { MNEM, ' ', OP (RD), ' ', OP (RA), ' ', OP (SIMM16), 0 } },
  & ifmt_l_lwz, { 0x0c000000 }
},

```

Figure 4.2: or1k-opc.c after changes

Figure 4.3: Bits (0x27) shifted to most significant 6 bits to make 0x9C

4.2.2 Resulting Output

The resulting output is a disassembly file with machine code that matches the instruction word format of the DMF RISC processor. This was obtained and can be seen the lines below in Figure 4.5 with addi instructions. When compared to Figure 4.4, its clear that the opcode for the addi instruction has been changed successfully. This was the only opcode change implemented, so this is the only opcode that will have a difference between Figure 4.4 and 4.5.

Figure 4.5: Disassembly of hello-world.c for DMF RISC processor

4.2.3 Changes Not Implemented

A full scale port to the back end of GCC was not implemented for this project. A full scale port requires much more time and a deeper understanding of the GCC back end, the ABI of the processor/GCC, and much more. This, however, would be how the DMF RISC processor would be able to run any C code compiled to it, without having to fix the instruction word structure of the DMF RISC processor. Additionally, had the opcode porting with the OR1k processor worked, it would have only been with certain simple instructions, such as the manipulation and data transfer instructions. Most likely no instructions that accessed memory would have been functioning, as well as any flow control instructions, like jumps and calls. These would all require a bit more manipulation to the OR1k files and the instruction word formats to match them to the DMF RISC processor (or vice versa). At that point, doing a full port of the back end of GCC to the DMF

RISC processor would make for a more simple fully functioning processor to compile C code.

Chapter 5

Tests and Results

This chapter discusses the results of the compiled C code run on the DMF RISC Processor.

5.1 Test of Basic Program

A program titled hello-world.c was used to test the process of compiling to the DMF RISC processor. Hello-world.c was a very short and simple program, and can be seen in Program Listing [I.11](#). The program simply initializes an int variable (x), sets it equal to 5 and then increments it by 1. This will be a simple enough program to see some instructions be used, but not too complicated for GCC to generate assembly instructions not supported by the DMF RISC Processor.

5.1.1 Compiled Using GCC

The C code was compiled, and the new opcodes were able to be seen in the machine code that was run in the DMF processor. The machine code that was output from compiling hello-world.c can be seen in [4.5](#). This assembly code was inputted into the mif file that the DMF RISC Processor uses to initialize the program memory, and the program was tested. The output was successful,

as can be seen in 5.1.

5.1.2 Run in Processor

Register 17 is the one the OR1k back end of GCC decided to use for the variable declared in the hello-world.c program. It can be seen after the program counter (PC) switches to 0x8, the output of R17 becomes 5, which is the reflection of the declared integer x being initialized to 5. Then, a few instructions later, when the PC switches to 0xB, the value in register 17 switches to 6, a reflection of integer x being incremented by 1.

Figure 5.1: Output waveform for hello-world.c run on DMF RISC Processor

5.1.3 Challenges of using OR1k Back end

There were a few challenges to using the back end of a processor that was not designed exactly the same as the DMF RISC Processor. The issues are as follows:

1. The supported instructions are not the same. The OR1k has instructions that the DMF RISC Processor does not support, and vice versa. Therefore, when the GCC compiles the c code into assembly for the OR1k, all functionality can not necessarily be ported over

to the DMF RISC Processor. This is one reason why it may be more beneficial to do a complete back end port of GCC rather than simply an opcode port. The solution to this was instructions that were unsupported by the DMF RISC Processor were given opcodes of 0 (equivalent to a nop in the DMF RISC) so that it would not be mistaken for a different instruction. These instructions were unused or irrelevantly used in the assembly code generated for hello-world.c

2. Originally, the DMF RISC Processor was a 2-operand processor (destination = destination (operand) source) while the OR1k is a 3 operand (destination = source (operand) source). The DMF RISC Processor had to be manipulated a bit to make into a 3-operand processor to match the OR1k assembly code GCC outputted. It was too difficult to change the OR1k back end to support the 2-operand instructions.
3. It was very tedious and time-consuming to find the part of the back end where the opcodes needed to be changed. Eventually, they were found in or1k-opc.c, but the way the opcodes were hard coded in made them difficult to find. As talked about in section 4.2.1, the opcodes were pre-shifted to be in the most significant 6 bits of the instruction word. The opcodes would have been much easier to find if they were put into the code as is, and GCC shifted them into the most significant 6 bit positions. As much work as porting the entire back end of GCC to a new processor would have been, it might have taken a similar amount of time to figuring out the OR1k back end enough to alter the opcodes to match the DMF RISC Processor.
4. There is no control over how GCC converts the C code to assembly. There were so many extra unnecessary instructions generated by the GCC compilation process that might be necessary for the OR1k, but weren't for the much simpler DMF RISC. Luckily, these extra instructions were able to be ignored in the DMF RISC, but it takes up extra program

memory space to have unnecessary instructions, which could be eliminated by doing a full port to the back end of GCC.

Chapter 6

Conclusions

This chapter discusses future work that could be completed as well as the conclusions from this project.

6.1 Future Work

In the future, the processor could be more fully integrated with the GCC compiler by improving two key things:

1. The instructions in the processor, and maybe the structure of their instruction words
2. The number of instructions/opcodes compatible with the GCC compiler

6.1.1 Processor Improvements

Since much of the time spent on this processor was to convert it from a 14-bit (original requirements from a class) to a 32-bit, extra critical instructions were not added to create a complete instruction set. Instructions such as a move instruction, as well as more data transfer instructions

that would add and remove items from stack (typically push and pop) were not implemented in this processor, but are used by the GNU Assembler.

Additionally, the processor could be converted to allow for three operands, a destination and two sources. Most processors operate like this nowadays, however, this processor was a very basic RISC design. It is much easier to port a processor to C, however, if it is capable of three operands.

Other components that would improve the processor functionality would be creating different features, as talked about in Section 2.1.2, such as out-of-order execution and branch predictions. Since this project was mostly to prove the availability of nearly any processor to be ported to GCC, these extra tasks were unnecessary, but could be implemented for future improvements.

6.1.2 More Compatible Instruction Words

The DMF RISC processor was not intended to be directly ported to GCC. Since instead the OR1k model was used and the simple binary of the opcodes were to be changed to be compatible with opcodes in the DMF RISC processor, the port was not done to its full potential. Using a tool called CGEN, new processors can be entirely ported to GCC for any C code to compile cleanly. In the future, this would be another main goal, to create all the additional files needed (typically a list of 7/8 files) to completely port the back end of GCC to the DMF RISC processor. This would most likely be an easier task if the aforementioned changes to the processor were first made.

6.2 Project Conclusions

Unfortunately, due to the development environment, the port of the DMF RISC processor to the back end of GCC through the OR1k files was unsuccessful. That does not mean, however, that

with more work, this could not be done. Even still, processors and compilers were explored in Chapters 2 and 3, and a deeper understanding of their workings was obtained. Every project attempt will not be successful, and sometimes it is the failures we learn most from. In the end, a solid processor was designed and redesigned, and a GCC back end was altered to what should have made the machine code compatible. Much was learned from this experience, and that is the main goal of any academic project.
